Abstract

There are many ways to model complex time series. The simplest approach is to increase the complexity, and thus, the flexibility of the model, for the entire time series. As an example, one could use a neural network. Another solution would be to change the parameters of a model dependent on the “state” or “regime” of the time series. A typical example here would be the Hidden Markov model (HMM). This paper combines the two concepts to create a Reinforcement Learning (RL) model that adds variables that depend on the state of the time series. To test the concept, the RL model is used with cryptocurrency data to determine the share to invest into the cryptocurrency index CRIX in order to maximize wealth. The results have shown that cryptocurrency metadata is useful as supplementary data for analysis of the respective prices. The Reinforcement learning model with regimes shows potential for investment management, but comes with some caveats.

1 Introduction

Asset returns behavior tends to change ever so often, making returns difficult to predict and portfolio management less consistent. This is especially true, if the asset class in question is based on cryptocurrencies. More complex models seem to have more success in the prediction process than the straightforward linear models, but they are difficult to interpret, and thus may not be replicable in a different dataset or environment.

In portfolio management, it is common to adjust the allocation weights based on the market

The second step trains three Reinforcement Learning models to determine the portfolio weights. One of them will have regime probabilities (the raw output of the previous step), the second one will only include the predicted regime (the regime with the highest probability), as well as a reference one with no regimes. This step uses the hourly data for the CRIX cryptocurrency index, also provided by the BRC.

The remainder of the paper will be structured as follows. Section [2](#) gives a literature overview. Then, Sect. [3](#) describes the methodology for both steps of the model. Section [4](#) shows the model configuration in practice for BTC analysis and CRIX trading. For the first step, it is evaluated, how the weighting changes the regime prediction, and how well both regimes in general as well as regime changes are predicted. Then, LIME is used to determine, which of the variables had the strongest influence on the decision making. For the second step, the trading of CRIX with the three different methods is evaluated and compared. Afterwards, the results are discussed in more detail and a conclusion is drawn. All

Another architecture that is often used with time series is the Convolutional Neural Network (CNN) (Lecun et al., [1998](#)). While primarily used for image data, CNNs have been adapted for time series by treating the data as a one-dimensional “image”. This allows them to capture local patterns and temporal dependencies within the data. Other techniques include Time Delay Neural Networks (Waibel et al., [1989](#)) and Attention Mechanisms (Vaswani et al., [2017](#)).

Reinforcement learning is a framework designed to learn the optimal actions over a period with the goal to maximize the reward over that period. It is often used in tandem with neural networks, as fully modeling Q-tables is often not an option. Q-learning is the simplest method, and it has many variations, such as Deep Q-Learning (DQN), Double DQN (Hasselt et al., [2016](#)) and Dueling DQN (Wang et al., [2016](#)). Common actor-critic algorithms are Deep Deterministic Policy Gradient (DDPG) (Lillicrap et al., [2016](#)), Advantage Actor Critic (A2C) (Mnih et al., [2016](#)) and Proximal Policy Optimization (PPO) (Schulman et al., [2017](#)).

3 Methodology

3.1 Data overview and preprocessing

The CRIX was initially developed by Härdle and Trimborn ([2015](#)) and further studied by Trimborn and Härdle ([2018](#)), Kim et al. ([2021](#)) and Hou et al. ([2019](#)). At the time of writing, the CRIX is provided by Royalton Partners.

The dominant cryptocurrency of the CRIX is Bitcoin (BTC), and the other coins in the index are highly positively correlated with BTC (Candila, [2021](#)), so, to simplify the calculations, only BTC metadata is used. The dataset ranges from 07.09.2015 to 31.05.2022 and is recorded daily. The data are extracted from the Blockchain Research Center³ (BRC) and is listed in Table [1](#).

The distress regime includes return quantiles (p_r) as a additional criterion. It was necessary to introduce it, as, unlike most assets, cryptocurrencies do not have a significantly negative skewness. In fact, the skewness of BTC in during the combined training and test sets is almost zero (-0.0362) . Thus, very high volatility in cryptocurrencies have a similar probability to result in positive returns as negative returns (Table [2](#)).

Table 2 Regime criteria

Overall, distress is determined using a distress score (p_d) , which is a combination of the volatility (p_{σ}) and return quantiles (p_r) :

Denote $(g \in G, G \overset{\text{operatorname{def}}}{=} \{1, 2, 3\})$ as a regime in the regime space, and (g_t) is the regime at time t . Then, in order to account for the imbalance, the weight (w_t) is introduced when calculating the loss function:

$$\begin{aligned} w_t = & (1 - \lambda) \frac{T}{\sum_{s=1}^T I\{g_t = g_s\}} + \lambda \\ & \frac{\sum_{s=1}^T I\{g_s \neq g_{s-1}\}}{\sum_{s=1}^T I\{g_t = g_s\} I\{g_s \neq g_{s-1}\}} \end{aligned}$$

(2)

where T is the total length of the time series in the training set and λ is a hyperparameter. Here, the first term corrects for the imbalance in the data and the second adds more weight to data points, where the regime switches. $(\lambda \in [0, 1])$ determines, how important regime-switching data points relative to other data points are.

$$\begin{aligned} l = -\sum_{t=1}^T w_t y_t \log \hat{y}_t \end{aligned}$$

(3)

In order to evaluate variable importance, the LIME algorithm is applied (Ribeiro et al. [2016](#)). The objective of the algorithm is to ensure both interpretability and local fidelity. This is achieved by solving the minimization problem:

$$\begin{aligned} \xi(x) = \arg \min_{g \in G} L(f, g, \pi_x) + \Omega(g) \end{aligned}$$

(4)

where L measures how close the explanation is to the prediction of the original model f , $\Omega(g)$ is the penalty for model complexity, and π_x is the magnitude of neighbourhood around instance x .

There are two ways to get (w_t) as a result:

- Winner-takes-all—the regime (g_t) with the highest probability will have a value of 1. For example, if regime “Low” is predicted, the input vector is (0, 0, 1).
- Weighted average—the values are probabilities of a regime being in place. This is essentially the raw output of the regime prediction stage.

Both of these options will be examined as separate models. In addition, a third version without any regimes is tested as a reference.

After the actions are received, the reward is calculated:

$$C_t = a_t \times B_{t-1} / P_{t-1}$$

4.1.1 Performance

At this stage, the data are split as follows:

- Training set: 08.08.2015–10.12.2019
- Test set: 11.12.2019–27.02.2022

The results for BTC are presented in the following tables for various metrics. As a reference for the main LSTM with weights, results for LSTM without weights and the ARMA-GARCH model are presented (Table [4](#)):

Table 4 F1-Score for different methods and λ

(d) Regime prediction for $\lambda = 1$

Bitcoin price plot with regimes. Regime breakdown: **zone 2**, **distress**. [RRL_Regime-Prediction](#)

4.1.2 Interpretation

The model will be interpreted using LIME (Local Interpretable Model-Agnostic Explanations) (Ribeiro et al., [2016](#)). LIME is a local surrogate model, i.e. it approximates the predictions of the black box model with an interpretable one. To determine the impact for each variable $\phi(x)$, values are perturbed, forming a new dataset, then the interpretable model is fit, such that the loss function L is minimized:

To determine the most influential variables, the LIME-values were calculated for every data point in the test set. A sample for a single data point can be found in Appendix [B](#).

For an approximation of the overall influence, the variables are ranked based on the absolute values (with rank 1 being the most influential one) for every data point in the test set. The mean of the values is then calculated for the final ranking, which can be observed in Appendix [B](#).

It is fairly obvious that previous regimes, price, volatility and drawdown all have a considerable influence over the current regime. However, metadata variables, such as sent coins, average transaction fee per day, average transaction value per day, number of unique addresses per day and average fee to reward. These variables mostly relate to trading volume

- Validation set: 09.07.2021–19.12.2021
- Test set: 20.12.2021–31.05.2022

Then, for all three variants of the model, the rewards are tracked as they are trained. They can be observed in Fig. 4. As the training process is stochastic, each variant is run five times to make sure the performance is consistent.

At least in the training set, the additional regime data does make a difference. Both the predicted regime probabilities and regime values significantly increase the reward compared to the “no-regimes” variant for the same training period, so it can be stated that the regimes do contain meaningful information for investment purposes.

As for the performance in the validation and test sets, the difference there is rather insignificant. The performance metrics for the training, validation and test sets can be observed in Table [6](#), while the reward development over time is shown in Appendix [C](#).

Unfortunately, it seems like the non-stationary nature complicates any kind of prediction task. Of course, it could just be, that regime predictions happened to be beneficial for the task in one time period, but not the other. It could therefore be a case of insufficient data, as regime changes are uncommon during the given time period.

Your privacy, your choice

We use essential cookies to make sure the site can function. We, and our 92 [partners](#), also use optional cookies and similar technologies for advertising, personalisation of content, usage analysis, and social media.

By accepting optional cookies, you consent to allowing us and our partners to store and access personal data on your device, such as browsing behaviour and unique identifiers. Some third parties are outside of the European Economic Area, with varying standards of data protection. See our [privacy policy](#) for more information on the use of your personal data. Your consent choices apply to [springer.com](#) and applicable subdomains.

You can find further information, and change your preferences via 'Manage preferences'. You can also change your preferences or withdraw consent at any time via 'Your privacy choices', found in the footer of every page.

We use cookies and similar technologies for the following purposes:

- > **Store and/or access information on a device**
- > **Personalised advertising and content, advertising and content measurement, audience research and services development**

architectures could be used. One example would be to split the network in a way that each network would train for a separate regime (see Fig. 5). To make the current version of the model more comparable to a buy-and-hold strategy and expand on its ideas, trading costs, leverage and short-selling could be introduced.

Fig. 5

6 Conclusion

A new approach to analyze the cryptocurrency market was introduced and applied to Bitcoin (BTC). Regimes were introduced that could be useful for further analysis. Using a weight system to counteract imbalance, a method was shown that could effectively predict future regimes with a high emphasis on when the regime switches. The LIME method was used to gain insight to what variables from the metadata had the most impact on the outcome. Those variables ended up being related to trading volume.

Afterwards, the regime prediction was used as part of a dataset in a reinforcement learning
